Acknowledgements

I'd like to take this opportunity to thank Reyer Zwiggelaar for agreeing to be my supervisor and for offering advice and guidance when it was sort. I would also like to thank both Reyer and Neal Snooke for their invaluable feedback on both my progress report and demonstration. These comments helped me understand the problems I was facing, what was going well and crucially where things could be improved.

Also thank you to Peter Maynard and Anika Rusnakova for their motivation and continued interest in my project. An extra thanks to Peter for his \LaTeX expertise and listening to my disjointed reasoning.

Abstract

MapWars is the culmination of an investigation into the feasibility of creating a location-aware, multi-player real-time strategy (RTS) game for a mobile platform. Consideration about which platform to support is presented with the final decision being to focus on Google's Android operating system.

The game combines strategic game play against multiple players in a persistent environment, where game play is based on map of Earth and users are restricted in game to their real world location. Giving each user the capability to create their own army and battle against other players within their local area.

At the same time consideration was made to protect each users privacy and create a fair gaming experience. Thus different techniques on how to prevent crafted requests designed to circumnavigate limits placed in the Android client.

Chapter 1

Background & Objectives

1.1 Background

Real-time strategy (RTS) games have a huge market on desktop environments, but have yet to make the break through into the mobile gaming market. This is mostly attributed to the complex control mechanisms that need to be executed precisely. A mobile devices form factor restricts the number of controls that can be presented to the user at any given time as well as the precision in which these commands can be issued.

RTS games are generally designed around large, expansive maps that cover a large range of environments and landscapes. The game map shapes how the game will be played, how involved the player feels and ultimately the engagement of players. These maps can take years to develop and result in one of the largest costs within the development process. So when coming up with an environment why not take advantage of a ready made one? That of planet Earth.

Building a game where the game play takes place on a map of Earth has a number of benefits. First is the scale of a map covering 510 million square kilometres of varying terrain and features. This scale also contains a huge level of detail that could not be achieved by a team of designers. Along side this there is the feeling of familiarity, unlike when starting a new game and having to teach the player about the environment, the user will already have a well formed model in their own head. Along with highly detailed knowledge about certain areas especially those within close proximity of their current location.

Mobile devices have a whole host of unique features and sensors that set it apart from other gaming platforms. One feature that has been widely adopted in a huge range of different applications is location. A users location can be easily determined with a number of different components present on most modern smart phones, these are a GPS chip and the mobile GSM network. Although location has been used extensively in applications it has yet to be utilized effectively as a key metric within a game. This extra information about the user would enable a game set around the physical world to be able to be integrated with the user. Instead of placing new users randomly on a unfamiliar map they can be placed in their real location. Thus giving them a chance to use their own knowledge of their surroundings to help them within the game environment.

1.2 Market

A worldwide RTS game that combines a map of the world and data gathered about the user combine to create a unique gaming experience and could add an entirely new dimension to the genre. This can also reduce the learning curve and thus shorten the time between installation and engagement. With the sheer number of applications available on a mobile platform combined with the ease and minimal to no cost of installing new applications, this is important to reduce the chance of the user simply finding an alternative.

1.2.1 Choosing a platform

The current mobile platform oligopoly results in their only being two viable platforms, Apple's iOS and Google's Android OS. The Android operating system, as of February 2013, had over 51% market share in the US [7]. Closely followed by the original and most established app ecosystem of Apple iOS. Even though there are other platforms, such as Windows phone and Blackberry, none of these have the market share allow them to be a primary platform of choice. Therefore choosing between the two platforms can be an important decision for mobile developers, both platforms offer their own unique advantages and disadvantages. Android on the one hand has the lead on market share offering a larger audience, although this will not directly affect engagement or return.

This years Developer Economics report [8] looks at all aspects of the mobile app market and is an invaluable insight into both the market and consumer trends. As well as evaluating the current market it also gets feedback from developers as to their experiences with different platforms as well as their success.

Figure 1.1: Developer Economics report [8] shows iOS as the leading platform among developers

As shown in Figure 1.1 iOS does indeed have a number of advantages over Android. Most importantly is the drastically increased chance of discovery as well as the expected return from applications on the iOS platform. For this project however less emphasis was placed on the success of the finished application and more on the process of creating it. Therefore the metrics of development cost and learning curve were considered to be more important. Aside from the Developer Economics findings there were a number of other more fundamental reasons as to why Android was the preferable platform. There was a certain amount of background knowledge and previous experience both with using and developing for the platform. The development environment had already been investigated and a small application developed prompting confidence in the ability to create and deploy something. Also a reasonable selection of Android devices were available for developing and testing purposes, which was favourable to using emulators and a single test device which would have been available for iOS.

The final consideration, which will be explored further in the following subsection, is that of not just overall market share but the scale of competition. IOS tends to attract the gaming market and as a result has a large selection of highly polished, top quality gaming titles. Whereas the Android market has a considerably smaller selection of games and these tend to be more basic and less graphically pleasing. Although this is changing as game developers migrate to Android it does give an advantage to new developers that might not be able to compete with the quality of iOS.

1.2.2 Android RTS Games

There is currently only a small handful of RTS games available for Android and of these most are unsatisfactory attempts. That being said there are a few well executed examples with the best examples coming from Noble Master Games who focus entirely on making these types of games for both desktop and mobile. The Stormfront series¹ consisting of Tropical Stormfront and Desert Stormfront are the closest Android offerings to a full RTS gaming experience. Originally released for Android both were later ported to PC, MAC and Linux then subsequently iOS, this was made possible due to the game being built with OpenGL. These games offered the best chance to evaluate what had been done before and see what is expected and what would work well for MapWars. By examining different aspects from game play to control options it is a good opportunity to pick up ideas for the UI and user interaction.

Tropical Stormfront was their first release for Android in December 2011 and for iOS in November 2012. It took the RTS experience and simplified it to aim it towards the casual gamers that make up a large percentage of the mobile market. Its simple sprite style isometric graphics, shown in Figure 1.2, are pleasing on the eye and make units and structures easy to identify. The uses of an isometric view also removed the complexity presented by 3D graphics, that could it make it difficult to control, while retaining a well designed style.

The game revolves around a series of short predefined missions. Each mission only takes a matter of minutes to complete and don't really require a huge amount of strategy this caters nicely for the casual gamer. There is also an option for multi-player games with a selection of modes ranging from skirmish to capture the flag, with one user hosting the game. The host is able to choose the game type, map and a number of other options, other users can then join the game.

¹<http://www.operationstormfront.com>

Figure 1.2: Screenshot from Tropical Stormfront by Noble Master Games

Unit control for example is cutback, users can control where units should move to as well as which enemies to attack but no other complex commands could be issued. A very useful feature was the ability to group units together and assign said groups to hot-keys along the bottom of the screen. Without these it was difficult to command a number of units in a controlled manner. As well as these assigned groups there was also the option to select units individually, by tapping that unit, or multiple units. Multiple unit selection was handled by tapping the green icon to the left of the hot-key buttons. This then enabled the user to drag over an area units selecting all within that area. It was important for MapWars to retain this level of control while retaining its simplicity. It could even be simplified further by removing manual targeting of enemy units, leaving this up to the game's AI system.

Another aspect that is missing is the ability to create and position buildings. Each map comes with a predefined set of bases that can not be altered or moved but enemies can capture other players' bases. These bases give players the ability to create new units and are also the mechanism for getting money. New units are built in a fairly standard process of selecting a base which in turn gives a range of units to build. Units cost a certain amount of money or resources to be built and the build process takes an amount of time to complete. After the unit has finished being built it exits the base and can be interacted with as usual. The lack of a build queue, in which players can make a list of which units they want built and they will be processed in turn, was found to be restrictive. Inclusion of a build queue seemed plausible while still maintaining the ease of use.

As mentioned previously in game currency is generated based upon the number of bases a player controls. Each base earns \$50 per minute, so the more bases captured the more money earned which in turn allows for building more units. Resource discovery, gathering and management are key aspects on PC-based RTS games but could present problems when being implemented on a mobile device. By removing these aspects the developers were able to speed up game play and in turn try to make the game more exciting. Unfortunately the direct correlation between number of units and victory made game play feel predictable as the player who captured the most bases inevitably won.

Tropical Stormfront takes a good approach that, as with a number of the other compromises, directs the game towards casual gamers by removing some of the complex strategy decisions.

They focused on fast based game play by setting the player up with a particular scenario with an established base and units with close proximity to the target. MapWars, although sharing many similarities, will ultimately be seeking a different target audience and game play style.

1.3 Objectives

MapWars attempts to focus on tactical game play with a mobile experience tailored to the users location. All game play will take place on a portion of a world map depending on the players location. While taking as many of the tactical aspects from existing PC RTS games with an elevated focus on resource gathering and long term tactical game play. Unlike some games that allow for fast paced "rushing" (a tactic in which a team will attack an opponent as quickly as possible as to surprise and overwhelm them) MapWars will encourage players to find and gather resources while building a substantial base and selection of units. This is in part due the sparsity of opponents in such a large environment. To try and compensate for the widespread nature of players, as well as the desire to recreate a real world experience, all players will play in a single persistent game. Being persistent all units will be visible even if their respective players are not online increases the emphasis on building a well formed and fortified base.

Problems may be present for early adopts and those in remote areas who will ultimately not come across other players for considerable portions of their experience. This will undoubtedly lead to players getting bored and leaving the game. To try and combat this possibility game play should try and be enhanced for non-offensive play. The focus on resource gathering, exploration and base development hopefully will be the main combat to this problem, giving players the ability to enjoy the game even without an opponent. Secondly the persistent and location-aware portions will help the game change and evolve as players move around. For example if a player from an unpopulated area spends their time enhancing their units could then travel to a more active area, such as a city, to engage with opponents.

1.3.1 Primary Objectives

The objectives listed are considered to be the minimum required to create a playable game:

- Ability to authenticate users
- Display all units on a map centred on the players current location, limited to a given range
- Location will be determined by all available sensors and the most accurate to be used
- Appropriate portions of the application will stop functioning when minimized, to preserve battery life and minimize data usage. The application should then return to a playable state when returned to
- Resource gathering
- Enable players to create units, within a given range of their current location
- Enable players to move units, within a given range of their current location
- Units will engage with enemy that come into range automatically

1.3.2 Expanded Objectives

If the primary objectives are completed before the hand-in date the following objectives will be considered. Each of these extra objectives are not essential to the project but would add extra depth to the game play and ultimately improve the overall experience.

- Altering the resources generated by each mine based on real world resources in that location
- Introduction of environment variables such as power requirements. Each structure will add to the energy requirements, if these aren't met the structures will not function.
- Ability to upgrade units and structures
- Extra unit and structure types
- Path finding that follows physical routes e.g. roads utilising a directions API
- Offline notifications

1.3.3 Limitations & Evaluation

Working with a mobile platform comes with a number of technical challenges and limitations. Most notably is battery life, modern smartphones are capable of a multitude of tasks that increases the demand on the phones battery. This combined with the lightweight, small factor demanded by consumers the battery life is severely limited. While developing MapWars it was important to keep this in mind and reduce the battery usage where possible. Certain areas that large power savings can be made, such as reducing the use of GPS sensors, can have a detrimental affect on accuracy or responsiveness. For this application the accuracy of the users location as they move around was not of a particular importance as it was used simply to locate them in the game area and not displayed directly. Therefore, with some small experimentation, the frequency in which the location was queried was tweaked to get a satisfactory balance between power usage and accuracy. Redrawing the screen is another drain on the battery so these should be kept to a minimum. The drawback with reducing the number of redraws is the possibility that the on screen movements of units and animations will become jolty and detract from the experience. Again experimenting with the delays within animation threads and reducing unnecessary redraws helps to keep the action smooth.

With over a thousand unique devices each offering a unique subset of sensors, screen sizes and features it is impossible to predict what features will be available on any device that will be running the application. For this reason it was important to take advantage of all possibilities while being aware of the limitations that may be presented. If a device does not support GPS or has it disabled, for example, it was necessary to find an alternative source of location data. Each source of data offered different levels of accuracy so again it was necessary to take this into consideration when determining which source to trust.

The success of this project will be evaluated primarily by it's ability to perform the tasks set out in the main objectives set out earlier in the document. Unit responsiveness when created and moved must be quick and consistent across devices. When a unit is moved on one screen the accuracy in which this is reflected on all other devices within proximity needs to be examined, with the smaller the difference resulting in a positive evaluation. With such a type of game this responsiveness can negate from the users experience and if it's too slow will frustrate and anger

the player. Advantage can not be given to users based on their choice of device and connectivity. The applications consideration for the environment, as explained briefly above, is also a critical point to evaluate. As well as just the battery usage of the application the amount of data sent and received also needs to be kept at a minimum.

These objectives are the only the basis and do not give a complete picture of the desired outcome. As well as these objectives the finished application must play well and be a pleasurable experience. These are difficult requirements to quantify and will rely heavily on user testing and feedback. By distributing the application amongst users unfamiliar with any previous incarnations will be the best measure of it's playability. Their ability to play the game without external interaction and their overall enjoyment are the most valuable measurements available.

Previous metrics are focused primarily on the clients representation of data received from the server, the server it self needs to be evaluated. The server is required to be able to handle multiple concurrent connections each issuing commands that may or may not affect the other connected users. It must also be able to control unit movements and automated targeting and attack mechanisms. All while validating users actions and preventing spoofed requests, crafted to give the user an advantage over other users using the Android client.

Chapter 2

Development Process

Due to a strict deadline and extensive possibilities the project offered it is important to choose a development life cycle that could both quick and flexible. It needed to be able to allow for rapid development in a controlled manor that would reduce the need for rewriting and refactoring of code. Therefore the methodology will revolve around an iterative life cycle. As the project is easily broken down into a small number of well formed sections these iterations are able to be well formed before development beings.

2.1 Introduction

The development life cycle chosen is that of Rapid Application Development (RAD). This process reduces the need to have a detailed specification or design at the beginning of development. Instead specification, design and implementation are all simultaneous. This life cycle follows more closely to the Spiral Model than that of a more traditional waterfall type life cycle. The Spiral Model, as defined by Barry Boehm [6], depicts an evolutionary style of development which still keeps control over the project. Unlike the waterfall model which requires a stringent and detailed design that needs to be followed throughout implementation. Only the highest-priority features are considered for each iteration. The chosen feature is defined, designed and implemented during the cycle. Each cycle results in a prototype of a portion of the final system that can be tested. From this prototype ideas can be tweaked and changed then defined and implemented. Then the next feature can be defined and so on until the desired system is completed.

The RAD life cycle is a further streamlining of the spiral model and only has four distinct stages. Firstly there is the requirements gathering stage where all parties agree on the scope and requirements for the overall project. This is followed by user design where users interact with the developers and create a set of prototypes that are then evaluated by the users. This step is continuous phase that sees the prototypes change and adapt to the users requirements. This phase works in tandem with the construction phase which sees the prototypes be integrated into the final application and tested. With the user still actively involved they can suggest changes and improvements as the application takes shape. After the application is completed the final stage sees its testing, integration and user training.

2.2 Modifications

The spiral and RAD models are defined as an evolutionary method therefore each iteration prototype should be delivered to the stakeholders. These stakeholders can then give their feedback which should be utilized in the next cycle. Seeing as this project does not have any stakeholders this crucial step can not be completed and therefore the model needed to be adapted from a evolutionary to an incremental one. To achieve this the stages were mapped out before implementation began resulting in a slightly increased amount of design. These stages were purposefully left as broad as possible to accommodate necessary changes that would present themselves as development began.

As well as removing the of reworking code by cutting out the feedback loop for each prototype, the user design and construction phases are combined. This single step would see prototypes being worked directly into the current code base. In this way extra development time would not need to be used to integrate the prototype back into the master branch. This combination by itself would slowly reduce the code quality seen across the application as ideas are tested, for this reason spike work is encouraged to be carried out before each iteration. These short spike work sessions should show up any problems and highlight more efficient ways that part of code could be implemented. This will then carry over into the main code when the feature is implemented. It is important to keep this spike work short and focused and full solutions are not the ideal outcome from it.

These modifications were made as a way to streamline development, reducing time spent in design and coding while not reducing code quality or flexibility.

2.3 Development Environment

It was decided to use the Eclipse IDE as the main editor partly due to it's popularity and abundance of information and also it's improved integration with the Android SDK. Google provide an Eclipse plugin called Android Development Tools (ADT) which provide a set of tools to streamline the development process.

Eclipse was only selected for the Android portion of development for the reasons stated above, for the remainder of the coding and other things Sublime Text 2 was picked. It offers syntax highlighting for all the most common languages as well as a vast array of plugins and features to speed up development time.

Version control was handled by Git providing both data assurance and branching. Git was chosen over other systems, such as SVN and Perforce, offering a more versatile workflow allowing for local version control with changes being pushed to the master instead of other more centralized systems. To utilize Git to it's full potential a web-based hosting service was used to both host the code and to add extra features such as issue tracking and wiki-style documentation. Both BitBucket¹ and GitHub² were used initially but GitHub was favoured over it's more comprehensive set of tools. Particularly useful was the wiki that was automatically setup allowing for detailed documentation and research. GitHub also offers a number of visualisations to easily view commits history and network showing the different branches and merges.

¹<https://bitbucket.org/>

²<https://github.com/>

The use of version control also helped with the rapid prototyping methodology by utilizing branching effectively. For each new feature being developed a new branch would be made where this development took place. Once development was complete these changes were tested and then merged back in to the master branch.

2.3.1 Hardware

Android offers a huge variety of hardware and is not just restricted to mobile phones. The OS can now be seen on tablets, set-top boxes, smart TVs and netbooks. However, mobile devices still have 96% of the market share with tablets following being with 64%, other devices only account for 20% of the market. To match this and the expected target market development was focused on both mobile phones and tablets. Originally a Motorola Atrix (v2.3) was picked for the main development device but after the first few months a faulty digitizer demoted this to a test device. A HTC Sensation (v4.0) was procured to replace the Atrix as the primary device. Experimentation and implementation for bigger tablet sized devices was done on a Motorola Xoom 2 Media Edition (v4.0). Other testing devices include a Sony Ericsson ST25i (v2.3).

The main development machine was running a 64-bit Debian based OS. Server hardware consisted a single virtual private server with 128MB RAM running Debian 5 32-bit.

Chapter 3

Design

3.1 Overall Architecture

It was clear from the outset that the server and client portions of the application should be developed independently. The two sections would also be ran independently of each other on different machines. To keep within the time scales of the project only one instance of the server will be running at any time. Multiple servers and load balancing would be ideal but not necessary at this time. The server was written in Python to be run on any compatible server. The client uses Java and designed to run on Android devices, the client then connects directly to the server using PUSH technology.

The client portion was developed by loosely following the wildly acknowledged Model-View-Controller (MVC) architecture. This design was chosen due to it being well known and understood speeding up the process of others understanding the code. Also it's rigid nature should help prevent chaotic and unstructured code. This pattern breaks the code up into three parts: the model which contains the bulk of the application logic; the view which handles changes to UI elements and the controller that handles events and negotiates communication between the model and view.

Nothing radical has been altered about the overall architecture from the progress report. It has simply been expanded while implementing new features.

3.2 Class Diagram

The class diagram for the client portion of the project can be found in Appendix B. The supplied class diagram is a simplified representation as it does not include variables or methods. The sheer amount of data was overwhelming when these were included and offered little extra insight into the client architecture. Classes are also not grouped by package as this made the diagram difficult to follow.

The servers architecture is considerably simpler and a diagram is not included in this report.

3.3 Use Case Diagram

Figure 3.1: Use case diagram

All actions that a user can perform are listed on the design user case diagram, Figure 3.1. This minimal looking list of actions is all the interaction required from a user. As the more complex behaviours are handled automatically by the server extra actions, such as attack, are not a concern of the user. This harps back to the overall ethos of keeping the game-play simple while retaining the features of a desktop RTS title.

3.3.1 Language

Developing applications for the Android OS restricts the language choice to just Java combined with an Android framework. This results in code written with Java syntax but are not entirely synonymous with Java. Code is converted from Java Virtual Machine (JVM) compatible code to code that can be run by Dalvik, the virtual machine used by Android. This conversion optimizes the code to be run on devices with limited memory and processing power.

For the server portion of the application it was important to choose a language that would aid in the rapid development methodology outlined for the project. Python is a general purpose high-level programming language that has a relatively small learning curve as well as some personnel background knowledge. It is designed with the express purpose of being highly readable by forcing well formatted code and using English keywords.

As the chosen hardware for the server is limited in processing power and memory it is important keep overheads to a minimum, which Python does fairly well. If Java had been used a much more powerful server would have been needed to support the same number of processes due to the overheads introduced by the JVM. However there would have been a number of advantages to using the same language as the client. These include a greater understanding of the language as it is used more extensively but more importantly would be code reuse. The client and server both perform many of the same procedures and could have sped up development time and increased accuracy and interoperability as the same packages could have been utilized.

The server also required a persistent data store to keep an overview of the users and units between downtime or server migration. The requirements specified matched closely to those given when choosing Python as the programming language.

- Non-proprietary
- Simple, zero-configuration database
- Relational makes things easy
- Lightweight
- Previous knowledge of SQL makes that a preferable language of choice
- Simple python implementation.

A nice looking option was KirbyBase¹ it matched all of the requirements and being purely python based was a plus. It is a flat-file database so was simple to configure and lightweight, it also had the flexibility of running both as part of an application or in a client-server configuration. Unfortunately development stopped in 2006 and the libraries website has since been taken off-line.

MongoDB² would have also been a nice solution as it supports a large proportion of the requirements and some other features ideal for this project. Unlike other options it is a NoSQL³ database which is an entirely different approach to database design than that of the standard relational database. This would have required considerably more investment of time to learn this new style of working. The main draw to MongoDB is that it offers geospatial indexing and queries. This allows the complex calculations of querying coordinates on a sphere could be handled directly by the DBMS.

The chosen SQLite solution has one long term problem that comes with not being able to run a client-server configuration. Thus restricting the application to a single server. As the popularity and interest in the game increases so would the demand on the server meaning that a more complex, distributed server model would be needed. This is outside of the scope of the current project so this was deemed to be an acceptable compromise.

3.4 User Interface

When developing any application for a small form factor it is important to consider how the user interface can be minimized, and to not clutter the display making precise controls difficult. This is especially important when trying to fit all the functionality of a RTS game within the small form factor of a mobile device. To get around this problem only the essential controls were included with only a portion of these being accessible from the main game screen.

The main game screen, shown in Figure 5.1, is entirely taken up by the game map where all unit interaction takes place. Overlaid on this map are the game controls consisting of a control bar (A) and a selection of controls (B). These controls have been minimized to take up as little space as possible while still being accessible and allowing the user the freedom of control desired. Unit

¹<http://wiki.python.org/moin/KirbyBase>

²<http://www.mongodb.org/>

³<http://www.10gen.com/nosql>

manipulation takes place directly on the map itself, units are displayed on a clickable overlay. Selecting a unit is as simple as tapping it, after selecting a unit it can be moved with another single tap in a free area of the map. When a unit becomes selected a health bar is displayed and an estimated attack range. The health bar is also displayed while the unit is under attack.

Figure 3.2: Isometric view of main game screen, showing separation between components

Chapter 4

Implementation

4.1 Client Implementation

4.1.1 Mapping

The first iteration focused on the central component of the application, the map. It was vitally important that an appropriate mapping solution was used. It needed to both be functional and beautiful. As it was the main influence on the applications aesthetics the cartography needed to be pleasing on the eye. As well as looking nice it need to function as an easy to read map that let units stand out clearly from other static mapped features.

Google

The original investigation focused on Google's own mapping solution. They provide a simple, easy to use interface to their own maps making it the obvious choice for any Android application. Their maps are accurate, up-to-date and very detailed.

Unfortunately there are a number of restrictions in place stopping their use in a number of situations. The most relevant of which is that they can not be used in an application that is not freely available to the public. Therefore restricting it's use in a paid-for application, such as MapWars may become. As the future of the application is uncertain it seemed desirable to steer clear of as many possible restrictions as possible. For this reason it was important to find a comparable alternative.

OpenStreet Map

OpenStreet map is a publicly contributed, free world map. It's growing popularity means that the majority of developed countries are mapped to an incredibly high standard, with other countries not far behind. With an acceptable level of detail combined with it's open standards made it the next most obvious source.

OSM has an API that allows it to be easily embedded into webpages but no native android SDK. A number of 3rd party libraries are available. The most complete and popular is that provided by MapQuest.

MapQuest are a mapping company that combines proprietary data and OSM data to create their own maps. They offer an Android SDK that gives you the option of which tile source to use. There are obviously restrictions to the proprietary data but if you opt for the free tiles then the same license is used as with OSM. The Android SDK available was designed to mirror the API available for the Google Map SDK. This made swapping out the Google Maps code and replacing it with the MapQuest code was trivial and problem free.

At the point in time of implementing MapQuest the design had called for the option to switch between satellite and road maps. MapQuest's main drawback, and more widely OSM itself, was it's lack of detail. The level of zoom supported was a number of levels less than that of Google Maps. These extra zoom levels would have made unit manipulation easier on smaller devices. Satellite images were the main concern as they were not available at the level of zoom required to make game play comfortable.

MapQuest was used as the mapping solution for a large portion of development and offered a stable platform. Once more of the functionality was in place user testing presented a number of problems with the map tiles being used. Most significant of which was a difficulty in being able to locate units among the details presented with the map. The sprites and colours being used to represent units were experimented with but none were clearly visible. The problem was with the design of the tiles being used and not necessarily the zoom levels present, although this may have helped alleviate the problems.

MapBox

One option available was to use a tile creator and host the map tiles on a server. This would be a costly and difficult solution to the problem. Hosting tiles is not a trivial task and require large amounts of storage and bandwidth.

MapBox offer beautifully customizable hosted tiles. They also have their own software called TileMill which allows the creation of bespoke tiles based on any data source which can then be hosted and distributed via their network. TileMill was based on a CSS style syntax allowing you to customise any visual aspect, from line widths, colours, strokes. It also had the ability to import data from any source giving the ability to build up rich tiles with as much detail as required. For MapWars only the most basic detail was required while using a simple colour pallet. The idea was to make any unit stand out against the map while still presenting all the information required to orientate the user with their surroundings.

Tiles could be loaded from MapBox using a standard URI syntax used by the most tile vendors. This allowed it to integrate easily into any mapping framework. All that was needed was an SDK that allowed custom tile sources. Such functionality was found in OSMDroid¹. Like with MapQuest, OSMDroid followed the same pattern as Google Maps allowing it to be easily placed into the application without only one substantial problem. OSMDroid was missing one function that was supported by both Google Maps and MapQuest. These function was key in selecting units so had to be reimplemented ... which was not difficult but took time. Assumption was made

¹<http://code.google.com/p/osmdroid/>

it would be as effortless as the previous transition. After integration was complete plugging in the URI to my generated tiles was simple and worked straight of the bat.

MapBox did not offer satellite imagery but the beauty and simplicity of the maps being used made up for this. It was also decided that the complexity of such maps would just present the same images as found with the default OSM tiles. Satellite images could always be added to OSMDroid by simply finding a tile source and using that and would have no affect on the functionality of the application.

4.1.2 Location

Detecting the users location accurately is fundamental and is used directly in controlling game play throughout the game. There are a number of difficulties presented when trying to accurately determine a users location. Firstly is the array of different providers available, each with their own unique characteristics, advantages and disadvantages.

Getting location updates within the application code was straightforward. Android exposes location updates by subscribing to providers via the LocationManager. A LocationListener can subscribe to any number of location providers and specify the frequency of updates required. Updates are sent after a minimum time and distance is reached. For this application battery life was more of a concern than getting high precise to the second data. So the minimum time between updates was set to one minute and the minimum distance sent to 2 meters. The minimum distance did not directly save battery but eliminates noise and recalculations based on small movements.

The network location provider uses the phones network connections to try and determine the users location. If they are connected via Wi-Fi the SSID (Service Set Identifier) is queried against Google's database of known SSID's, returning a location. This database is built by crowd sourcing data from Android handsets. When enabling location services on an Android device the following messages is displayed, Allow Google's location service to collect anonymous location data: Periodically the users location data from GPS, Cell-ID and Wi-Fi is broadcast along with details about available Wi-Fi connections to Google. This data tends to be fairly accurate, however when not connected to Wi-Fi the network location provider returns a location based upon Cell-ID. This technique identifies the mobile network providers cell the users is in. The location of each Cell-ID can be located so an estimated can be produced for the users location. Unfortunately cells can be very large making this method very inaccurate, however this tends to be around 1km and even less within rural locations [14] making it acceptable for this application.

When taking location data from a variety of sources it is critical to have a process to determine which is the most accurate to the users current location. The developers guide on location strategies [2] was an ideal resource to understand how each different provider worked and ultimately how to combine them to produce the best outcome. Each provider will gather data at different times and to a different level of accuracy. Whenever this data is processed a judgement needs to be made into whether this is more reliable than the currently known location. This was made based on its accuracy and age.

The process used to determine the most accurate location was adapted from an example provided in the developer guide. As shown in figure 4.1 each new location is compared against different aspects of the previously known location to decide if it is more or less accurate. If no previous location has been noted then the new data is taken to be the most accurate. If there has been a

previous location the new location is only used if it is significantly newer else, if it is not significantly older, the accuracy of the two sources are compared. Each time a new location is received it comes with an estimated accuracy. This accuracy is measured in meters and is defined as the radius of 68% confidence [3]. Meaning that there is a 68% chance that the user is located within a circle with a radius of the accuracy, mapped around the supplied location.

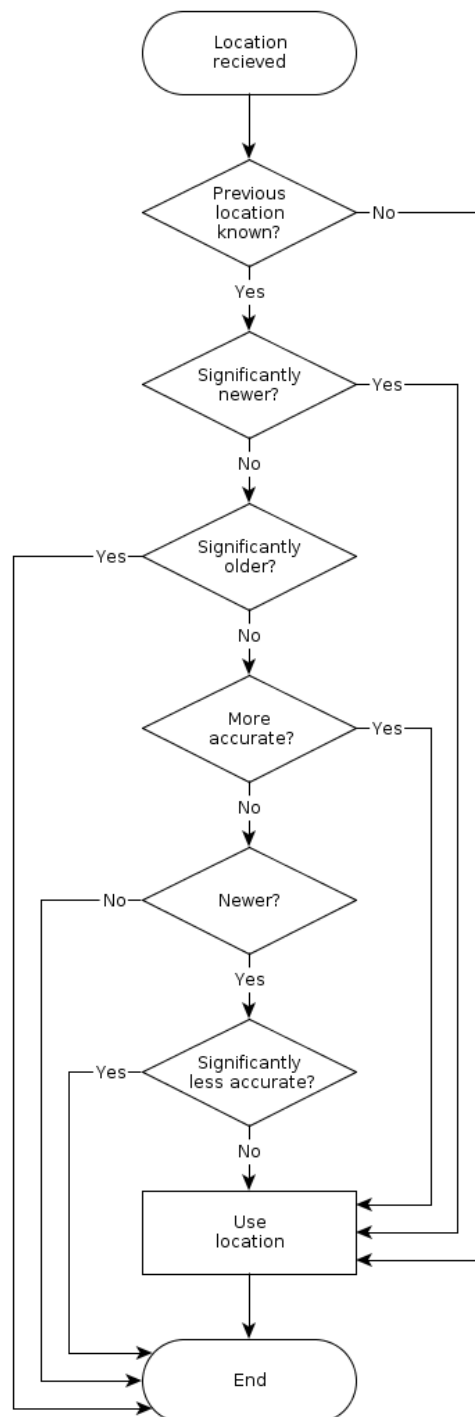

Figure 4.1: Flowchart showing the reasoning involved when selecting a location provider

4.1.3 GUI

Device Specific Layouts

Android layouts offer a variety of options to provide different layouts to different devices. The most basic of which is to make a fluid layout that stretches to fill the screen using `wrap_content` or `match_parent` widths. As well as these options there is a variety of dimension units to allow layouts adjust to different devices. The most useful of which are density-independent pixels (dp) which are units based on the physical screen size. These units relates to one pixel on a 160 dots per inch (dpi) screen. So the ratio of dp-to-pixel changes to match a devices dp. There is also a derivative of dp, scale-independent pixels (sp). Sp is the same as dp but also takes the users font size preferences into account.

Although flexible layouts allow for a single layout to be used across devices it does not allow for different layouts to be specified. This is possible using size-specific resources [4]. By placing layouts in a folder `layout-large` these layouts will only be used for devices classified as large, where any device below this category will use layout files in the standard `layout` folder. These size qualifiers are predetermined and static As of Android 3.2 new smallest width based qualifiers were introduced using the devices dp as a reference. Layout files placed in a folder `layout-sw<n>dp` are used only for devices with a minimum width of n dp. It is noted that a typical 7" tablet has a minimum width of around 600dp, this is the size opted for in this project. As described in the design it was important to differentiate between the phone and tablet layouts as both offer users a different experience.

While working on two separate layouts a large amount of code was being repeated and as features were added both layouts had to be updated interdependently. This seemed like a waste of time so a neater solution was investigated. A simple yet elegant solution was found that allowed different layouts to be combined together using the include tag.

For example the game screen added components to a basic map view, shown in figure 5.1. The layers A and B are stored in separate files with two versions, one for each device. A simplified version of the file structure used can be seen in figure 4.2. `map.xml` is the layout file used by the game activity, which in turn includes the header (A in figure 5.1) and controls (B in figure 5.1) layout files. These are automatically loaded from the correct folder on inclusion so the tablet layout is shown for devices with a width greater than 600dp.

Figure 4.2: Simplified layout file structure

Device Based Orientation

From the design specifications for the GUI it was decided that devices of different screen sizes should not only have different layouts but also different orientations. Forcing an application wide orientation is straightforward. By setting `android:screenOrientation` to `landscape` in the `AndroidManifest.xml` file will keep the orientation landscape. Unfortunately there is not such a simple solution for setting the orientation based on device.

It is also possible to set the orientation within the application code. Each activities orientation can be set using `Activity.setRequestedOrientation`. Once it has been determined which device is being used it is then possible to set the relevant orientation, as shown in figure 4.3. It is to be noted that this changes the orientation for this activity, not the application. As the application is built of multiple activities this needs to run whenever a new activity is created. All activities have access to the `MainController` and call `setActivity` on creation, so this seemed like the most logical point to do this.

```

if (Utils.isTablet(currentContext)) {
    currentActivity.setRequestedOrientation(
        ActivityInfo.SCREEN_ORIENTATION_LANDSCAPE);
} else {
    currentActivity.setRequestedOrientation(
        ActivityInfo.SCREEN_ORIENTATION_PORTRAIT);
}

```

Figure 4.3: Setting screen orientation based upon device

The code behind `isTablet()` was based upon an online solution [5] to differentiate between big phones and small tablets. It appears that the best approach is to calculate the screen size by dividing the pixels by the devices dpi. A diagonal screen width of 7 inches was selected as the cut off point between classifications. Anything over this felt more comfortable in landscape orientation and are mainly operated in this manor.

9-patch Images

9-patch images are the ideal solution for designing images that are intended to scale. As this application will be run on a variety of devices they were desirable to investigate further.

These standard images contain information that can be used to define how the image should be have when scaled. Surrounding the design are four separate, pixel wide lines that indicate which sections should scale. Those located on the north and west edge mark the area that should be scaled. When the image is stretched the areas not in-line with these marks stay as they are whereas the marked out area stretches to fill in the gap. As the side of this image is uniform it makes no difference if just one pixel stretches or a large portion, so just a single pixel was used. The other marks, east and west, are there to indicate the fill area or in other words the free space within the image. In this case the area defines where the input text should be positioned as not to

Figure 4.4: Text input 9-patch background image

overlap to overlay the rounded corners and styling. Using the file extension `.9.png` automatically tells Android that this is a 9-patch image and it will use the guides to scale the image.

Only one 9-patch image was used during this project and that was to keep a consistent look across devices for text fields. When styling a text field it is important to give the user feedback regarding which input is currently selected. For this a background was created with multiple drawable items, one for when the input has focus and the default. The image used for focused inputs is shown in figure 4.4 showing a green glow around the input.

4.1.4 Communication

To start developing the communications portion of the client code a simple server was required. For this a basic echo server was created that simply received data and responded with a static response. With this in place it was possible to start experimenting with different technologies. The first big decision being between using push or pull technology.

Both push and pull are types of network communication and describe the interactions between the client and the server. Pull is the technique where each interaction is initiated by the client, the client sends the server a message and the server responds. Push on the other hand allows the free transmission of data in both directions irrespective of previous communications. Typically in a push scenario the client subscribes to a server so when new content is available the server pushes the data on to the client. In a push scenario data is received by the client as close to real-time as possible, whereas when using pull the server has to wait for the client to request data before it is transmitted.

In the fast pace of online multi-player games it is vital to update all clients with out players actions as quickly and accurately as possible. The standard approach is to have a highly coupled client-server architecture relying on push technology to keep all clients updated. However after reading a study [11] examining the feasibility of using RESTful architecture for a massively multi-player game. RESTful architecture would take advantage of pull instead of the standard push. It was conclude that it is possible to support the kind of user and interaction loads found in popular multi-player games using REST, if caching and other techniques were utilized.

REST lends itself to scalable applications due to its stateless communication, meaning that re-authenticate is required for each request. This re-authentication enables each request to be processed by any server in the network, irrespective of any previous interactions. Creating a scalable server architecture would be a desirable goal any multi-player game as it allows the architecture to quickly adapt to influxes of users. Each request could be received by a transparent proxy that would forward the message on to one of the servers residing behind it. The server could then process this request, responding data will then relayed back through the proxy to the client. Having each request hit the proxy before being allocated to a server would help load balance the servers, distributing activity equally between servers. Adding in the possibility for the proxy to avoid overloaded machines until they finish their current requests. When using push this balancing becomes more complicated as the proxy will direct each new client to the least loaded server. As users connect and part one server may become overloaded as its connected clients continue to interact heavily while other servers sit idling. This would have to be combated by closing connections and having them re-established with a different server when one comes under too heavy a load.

Original spike work focused on implementing such a pull based system. It was found that, al-

though the papers conclusion was achievable, the number of requests required to make the game playable was huge. Creating and tearing down connections is a costly and slow procedure. These drastically increased the battery usage, to try and combat this the number of updates were reduced. When reduced enough to make a difference to this battery usage the game play became outdated so quickly it was impossible to play an accurate game.

It was decided to instead opt to use a single persistent socket between the client and server. This connection allowed free passage of data both up and down stream without having to reconnect or re-authenticate. This improves both speed and efficiency. When data is received by the server, if appropriate, it is instantly transmitted to all relevant clients. Meaning data received by the client is always as fresh as possible, while only sending network traffic when new data is available. This form of communication was implemented using raw sockets. A thread executed every 100 milliseconds reading a buffered line of input from the socket and passing this to a handler in the main controller. The problem with this approach is that it does not entirely handle disconnects or changes in network interface. Resulting in some unexpected behaviour when the user loses connection.

4.2 Server Implementation

4.2.1 Communication

Server communication was handled by the twisted networking library which is a event-driven framework allowing for rapid implementation. Only two events were eventually used to track connected clients and receive data.

To enable the push style of communication it was important to keep an up to date list of connected clients. When a new connection is established the first command received must be an authentication request. Once a connection is authenticated a user object is created and stored in a list of connected users. After the connection is authenticated it can then start making other requests. If one of these requests affects game-play by creating, moving or attacking a unit all other units, within range, are notified. By looping through the list of connected users those in range can be isolated and their. A message is then transmitted to the connection obtained from their object.

4.2.2 Geospacial Function

Most of the functionality of the server requires calculations based upon coordinates and distance. These functions are not available inside Python so a class containing these methods was created. The mathematics involved in each function was aided by an detailed on-line resource [10] explaining how to perform different calculations on a sphere. Output from the resulting class was far from accurate as it took a simplistic view of the earth as a perfect, smooth sphere of a fix radius. It was deemed accurate enough for the required purpose.

A serious amount of time was wasted by unexpected output when requesting a bounding box around a coordinate. This was due to inexperience with the language rather than any errors in the theory. The function relied on radius been calculated by dividing the desired radius by the radius of the earth. This simple division was the root of the issue. As both values being divided were supplied as integers the returned value was also an integer. Due to the expected result being very

small and precise instead of resulting in 0.0000123, for example, 0 was the given result. This 0 was then used to calculate the size of the bounding box meaning it was non-existent. By adding a decimal to one of the values being used it changed it from an integer to a float thus returning a float of the correct value. Once this had been added the function worked exactly as anticipated.

4.2.3 Artificial Unit Control

Unit locations and other details are stored and queried directly in the SQLite database. As well as simply storing and transmitting unit locations the server also handles the movement of units between way points and confrontations between units.

Unit movement is handled by a fairly simple formula that took longer than expected to reach. The final algorithm was based upon Bresenham's line algorithm², one of the simplest solutions but results in fair accuracy and minimal computation. By combining the algorithm with a calculated number of steps it was possible to visualize unit movement between two points at a consistent speed. This was achieved by basing the number of steps on the distance remaining so that as the distance decreases so does the number of steps remaining to take before the unit has reached its destination.

After all units have been relocated each unit looks for enemy units within range of its weaponry. Selecting the closest unit and removing health from it. This had the intended result but led to rigid, predictable and uninspiring behaviour. To make the combat more interesting the order in which units attacked was randomized as well as adding a probability to whether the units attack would be successful. Combined with limitations placed upon fire rates of each unit created a more dynamic experience. An uncomplicated but essential bit of reasoning that improved game-play drastically.

²http://en.wikipedia.org/wiki/Bresenham's_line_algorithm

Chapter 5

Testing

5.1 Overall Approach to Testing

Testing consisted mainly of manual functional testing due to both a short time scale and visualization of data. As most of the functionality consisted of echoing unit location data to multiple users it was easier the test based on user perception. Some automated tests were created, most notably that of the stress testing of the server instance.

5.2 Client Testing

5.2.1 User Interface Testing

The Android SDK comes bundled with a number of automated user interface testing tools¹. These functional tests allow for automated testing of component behaviour as well as responding correctly to user actions. This projects interface contained very few components that actually performed very little functionality. One possible candidate for such testing could have been the map views response to using the zoom controls. This however was considered to trivial, along with any other possible test cases, that the time was not invested to automate this process. These functionalities however formed a key role in using the application so would have been quickly picked up by both developer interaction and manual testing.

5.2.2 Manual Testing

Most white-box testing of the client was performed using Androids built in logging methods. LogCat is a greates tool that is bundled with the Eclipse plugin. LogCat allows the tester to view log data in real time from the application running on connected hardware. As well as being an invaluable development tool allowing for real-time debugging errors, it also can be utilised to verify that functions are returning correct values and the application flow is as expected.

¹<http://developer.android.com/tools/testing/testing-ui.html>

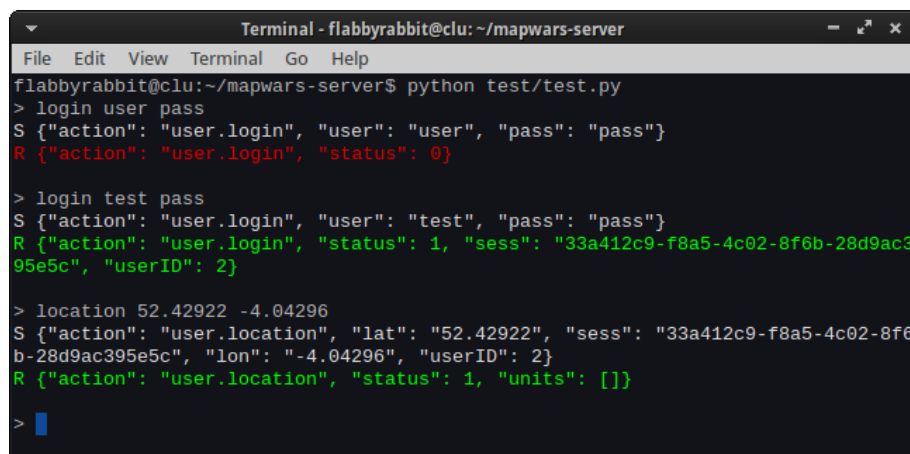

Acceptance testing was the most useful testing performed as it validated if the application functioned as intended at the highest level. Each bit of functionality was tested after it's completion and integration into the main application. If a part of the application was not functioning as expected white-boxing techniques were used to pinpoint the location of the problem and rectify it. Even though these tests were only intended to test the new sections of functionality it usual repeating steps from all previous tests to get to that point, thus any problems in previous functionality would be picked up. As well as testing if each section acted as intended it was important to test the application in its entirety. Therefore after each iteration had passed its specific tests a series of steps were carried out intended to cover all currently implemented functionality.

This approach to testing allowed for an increased amount of time spent focused on developing features, however this was possibly at the compromise of the integrity of the application. The use of JUnit to automate the testing of some features would have been a more reliable form of testing. Also investing time in learning and implementing Android specific testing tools, such as UI testing described previously, would have aided this assurance.

5.3 Server Testing

5.3.1 Message Generator

While developing portions of the server program it would have been impractical to use the production client as a primary testing tool. For this reason a small testing suite was created in Python which can be seen in Appendix C. This tool creates an easy to use command line interface program that could impersonate the natively running Android client. User input is wrapped in the necessary JSON object and transmitted to the server. Both the sent object and received object are displayed on screen to aid in debugging.

```
Terminal - flabbyrabbit@clu: ~/mapwars-server
File Edit View Terminal Go Help
flabbyrabbit@clu:~/mapwars-server$ python test/test.py
> login user pass
S {"action": "user.login", "user": "user", "pass": "pass"}
R {"action": "user.login", "status": 0}

> login test pass
S {"action": "user.login", "user": "test", "pass": "pass"}
R {"action": "user.login", "status": 1, "sess": "33a412c9-f8a5-4c02-8f6b-28d9ac395e5c", "userID": 2}

> location 52.42922 -4.04296
S {"action": "user.location", "lat": "52.42922", "sess": "33a412c9-f8a5-4c02-8f6b-28d9ac395e5c", "lon": "-4.04296", "userID": 2}
R {"action": "user.location", "status": 1, "units": []}

> 
```

Figure 5.1: The message generator tool in action

Although this tool automated the process of generating and transmitting messages it still required the user to decide what is to be sent and to verify what is returned. No logic is presented with the testing tool to decide if the response received is the expected response or not.

5.3.2 Stress Testing

Measuring the stress imposed on the server from increased load was a useful indicator into both the efficiency and stability of code but also the validity of choosing a single server setup. Stress testing was the main automated testing tool with this project. It was a modified version of the message generator tool mentioned previously but removed all user interaction. The program created a connection to the server, registered a user, logged in and set its location. From here it would randomly create and move units at a predetermined fixed interval. By running multiple instances of this program it was possible to simulate any number of connected users performing a heavy load of interactions with the server. To add to this as all units were created within a small area combat between these units was high adding to the stress on the server.

The use of such a test was important to check the efficiency of the server and to try and determine the number of connections each instance could withstand. It was found that memory usage was only effected by unit creation and at a linear rate of 5kb per unit. It was also important to use such a tool to test the clients ability to respond to large volumes of data. While running the stress test against the server the client was also examined running on a mobile device. The minimal increased sluggishness of interactions within the application demonstrated that the client was more than capable of handling large numbers of players in a small area.

5.4 User Testing

To get a feeling for user perception of the application it was given to small focus groups at key stages through out the development process. Feedback was gathered to try and determine their feelings about both game-play and overall experience. Below are two users comments after the final iteration of development.

Name:	Peter Maynard
Device:	Sony Ericsson ST25i
Android version:	2.3.7 Gingerbread
Screen size:	3.5 inches, 480 x 854 pixels
Comments:	Had fun playing around with generating units and fighting them. There was a limited amount of units which was a shame, but can see the potential and look forward to playing with more users.
Name:	Anika Rusnakova
Device:	Motorola Xoom 2 ME
Android version:	4.0.4 Ice Cream Sandwich
Screen size:	8.2 inches, 1280 x 800 pixels
Comments:	I can see this game becoming very addictive once there are more options and opponents. The map style is perfectly suited to the game as are the simple interface elements.

Chapter 6

Evaluation

While providing a challenging set of targets the final application demonstrated a working prototype of the original concept, creating a multi-player location-aware game for a mobile platform. This was completed while taking into account consideration of the limitations presented by such a platform. A great deal was learnt about both Android development and Python fundamentals.

6.1 Primary Objectives

All primary objectives were at least partially implemented, with most being fully integrated. The only objective not fully covered is the ability to place the running application in the background and then restore it.

User accounts, both registration and authentication, are implemented on both the server and client. User accounts are persistently stored on the server-side, while session based authentication is used to keep track of connected clients.

The ability to create units is fully functional, with these actions being quickly reflected on other players devices. Players can then select their units and instruct them to move to a new location. With two modes available to select units this processes is simple and flexible. Units will then start travelling towards the target location, again with other players devices displaying these updates accurately. Units automatically engage with enemy units as they come into range with dynamic consequences.

A simplified form of resource gathering was adopted taking inspiration from Tropical Stormfront's model. Placing of mines automatically gathered a fixed amount resources at regular intervals. Although not being the intended solution it was a satisfactory compromise to get the functionality in place on time.

6.2 Expanded Objectives

Unfortunately none of the secondary objectives were reached due to the time scale of the project. Some of these objectives would be fairly trivial to implement but were decided to be left out for the sake of improving the fundamental objectives.

Adding additional units and structure types with individual characteristics would be the easiest of these to add and would require minimal alterations to both the client and server. Removing hard coded characteristics in favour of inherited values from a list of available types. Once these alterations were made it would then be possible to add any amount of different types without altering the underlying code. Likewise upgradable units and structures and environment variables would have required a similar amount of investment.

Offline notifications would also have been possible using Google's cloud messaging (GCM) service [1]. This service allows data to be transmitted to Android devices via Google's servers. Data is limited to a 4kb payload so would most likely have been a simple notification message. This message could then be disabled to the user from which they can decide whether to open the MapWars application and respond or ignore it. The nice feature of GCM is that messages are delivered to applications even if they are closed, therefore allowing for notifications to be displayed when the application is not in use. This would be an important feature in a release version, increasing user retention, but for this prototype it was not an integral part.

The other secondary objectives were far more ambitious. The data is widely available for both the path finding and variable resources ideas but incorporating these into the project would be more difficult. MapQuest, for example, offer a limit-free open directions API [13] from which it is possible to get a series of way points. These coordinates represent the route between two supplied locations. Unfortunately mapping these to unit movements would have required a considerable amount of investment in both the client and server portions of the application.

6.3 Critical Evaluation

Retrospectively the initial objectives were more optimistic than first imagined. That being said they were necessary to get a full experience of what such a game would require. The overall result was a playable prototype that gave a feel as to what a completed version would be like. It was encouraging to see that there were no major complications during development and the result was an enjoyable experience to play.

Relating back to previously specified evaluation criteria a major objective was to enable the application to run comfortably on a wide range of devices and to limit battery use. The two separate layouts for different size devices allowed for a comfortable experience on both small phone form factors and larger tablets. The decision to change orientation between the two layouts turned out to be instinctive, with this being the natural behaviour. As for battery life, at each stage decisions were made to try and improve battery performance. The resulting application still drains battery life at a noticeably increased rate this is not as drastic as originally envisaged. This rate still allows for extensive game-play while realistically the game would not be actively played extensively. Instead users would opt to leave their units where they are and instead wait for notifications (not implemented) to which they would open the application and make the necessary moves. This alternate playing style should have been realized earlier and taken into account.

A major area in which this project is lacking is in comprehensive testing. This is proof of the difficulty of maintaining a consistent approach across a development life cycle. Testing should have been an integral part of each iteration cycle, unfortunately this was not followed as rigorously as it should have been. This can be entirely blamed on the developer wanting to focus more attention on completing functional aspects of the code rather than testing. The availability and

domain knowledge of JUnit would have made this a not too difficult task and may have, unnoticed by the developer, increased productivity and accuracy. That being said no major problems were encountered directly related to the lack of such testing. This could be attributed to the nature of the application which requires a fair amount of observational testing during development; helping spot any errors quickly.

6.3.1 Known Bugs

Current path finding techniques on the server-side are rudimentary. Although fulfilling the requirement of moving a unit from point A to point B it does so in a straight line, not taking other units into account. This simplistic approach leads to units manoeuvring directly over the top of other units. No obvious solution, within the currently implemented process, was found to prevent this. It would have been possible to create way points the unit could follow that would create a non-linear path. This would avoid static obstacles but could not predict the movement of other units. To effectively avoid moving units a more sophisticated intelligent system would need to be devised as well as an increase in server-client communication.

This path finding also leads to another bug which is most apparent when two units are selected at the same time and directed to the same location. The two units will reach the end location and position themselves in the same location. At this point it will become impossible to select just one of these units as they occupy the same space. Resulting in two units merging into one without the ability to separate them. A solution could be imagined where when the server receives a request to move a unit into a location; this location is then checked against other units positions and target positions. If this request matches with another unit the target location will be modified. So that the unit comes to rest as close to the target location while not impeding on any other units.

Using a single persistent connection between server and client results in a sometimes unstable connection. Procedures are in place to reconnect lost connections but this does not appear to cover all circumstances in a satisfactory manner. When connection is lost and re-established all updates in-between are lost and there is no mechanism to re-sync the client with the server. This lack of ability to get old updates leads to another bug relating to placing the application in the background. To conserve battery life this action pauses all threads and disconnects from the server. When the application is later brought to the foreground threads and connection are re-established but by this point the client is out of sync. It would be desirable in both circumstances to have a method that gets a complete snapshot of the environment from the server. With this data all aspects could be updated to their current state.

6.3.2 Improvements

Due to the time frame available a number of features, as mentioned before, were not implemented. By implementing these expanded objectives the overall game-play could be improved.

Fixing the known bugs would be a high priority, especially the ability to place the running application in the background while keeping sync with the server. This is expected to be a natural behaviour of the end user and would lead to frustration if presented in its current form.

The graphics within the Android client require more work as they are currently flat images. Adding

in animation of units and scenery as well as visualizing attacks would add a lot to the experience.

Reworking the server architecture to be scalable and work across multiple servers would be necessary before release. These alterations would see the server being able to hand much larger amounts of traffic. It would be desirable to create a transparent proxy that routed connections to one of a number of servers, each running independently of the others. These servers would simply handle updates and responses and would delegate the AI portion of functionality to a separate machine. To make all this possible a different DBMS would be required to allow multiple connections from different servers, this would be running on a dedicated machine.

6.4 Summary

The resulting application is a solid example of how such a concept could be executed on a mobile device. It is satisfying to see that it is possible to create an enjoyable and feature rich RTS game within the confines of the platform. With some further investment of time it entirely plausible that MapWars could, and will, be a marketable game. While playing the game it is clear that the number of active players would be the deciding factor between user enjoyment and disappointment. The persistent nature certainly aids this as attacking units left behind by off-line players is just as engaging as if they were on-line. The experience of working on such a project has greatly increased understanding of both Android and Python development, migrating from a relative novice to having a comprehensive knowledge of both.

Appendices

Appendix A

Third-Party Code and Libraries

1.1 Images

The unit iconography was taken from <http://game-icons.net> which is a resource of thousands of free, customizable icons. All icons are provided under the terms of the Creative Commons 3.0 license.

Unit themselves images were borrowed from a sprite sheet found at <http://i54.photobucket.com/albums/g85/FeatherofDeath/ImperialSheet-2.png>. No license was found accompanied with this sprite sheet so these images are used solely for testing and would not be released with the final product.

Other icons were from <http://icomoon.io> which creates custom icon fonts but also allows for icons to be exported as image files. Icons used are provided under the terms of the Creative Commons 3.0 license.

1.2 osmdroid

Osmdroid is the library used to get map tiles into the application, replacing the standard Google Maps API. The library can be found at <http://code.google.com/p/osmdroid/> and is licensed under the Apache License 2.0 and the Creative Commons 3.0 license.

1.3 Detect small tablet vs big phone

The following code was taken from an answer on StackOverflow [5]. Small alterations were made to the code, such as moving the `screen_size` variable to a hard coded value with the function.

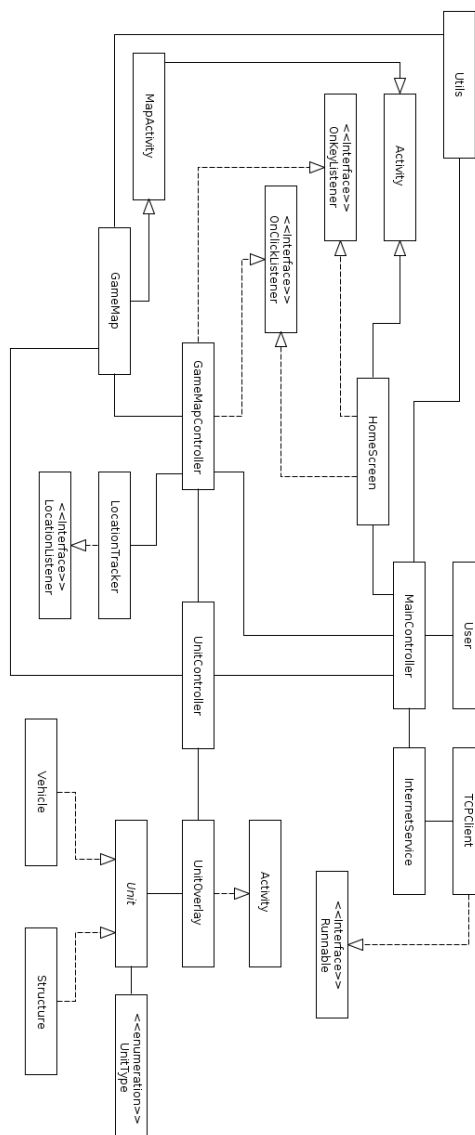

```
public static boolean checkScreenSize(Activity activity, double
    screen_size)
{
    Display display = activity.getWindowManager().getDefaultDisplay();
    DisplayMetrics displayMetrics = new DisplayMetrics();
    display.getMetrics(displayMetrics);

    int width = displayMetrics.widthPixels / displayMetrics.densityDpi;
    int height = displayMetrics.heightPixels /
        displayMetrics.densityDpi;

    double screenDiagonal = Math.sqrt( width * width + height * height
    );
    return (screenDiagonal >= screen_size );
}
```

Appendix C

Server Testing - Message Generator

```
#!/usr/bin/env python
import socket
import sys
import time
import re
import json

HOST = 'localhost'
PORT = 4565

sess = None
userID = None

try:
    sock = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
    sock.connect((HOST, PORT))
except socket.error, msg:
    sys.stderr.write("[ERROR] %s\n" % msg[1])
    sys.exit(1)

while True:
    n = raw_input("> ")

    msgDic = dict()

    if n == "exit":
        break # stops the loop
    else:
        match = re.findall("^[^s]+", n, re.M|re.I)
        if match:
            if match[0] == 'login':
                msgDic['action'] = "user.login"
                msgDic['user'] = match[1]
                msgDic['pass'] = match[2]
            elif match[0] == 'register':
```

```

        msgDic['action'] = "user.register"
        msgDic['user'] = match[1]
        msgDic['pass'] = match[2]
        msgDic['email'] = match[3]
    elif match[0] == 'location':
        msgDic['action'] = "user.location"

    if len(match) == 3:
        msgDic['lat'] = match[1]
        msgDic['lon'] = match[2]
    else:
        msgDic['lat'] = '52.35184333541474'
        msgDic['lon'] = '-1.966477632522583'
    elif match[0] == 'unit':
        msgDic['action'] = "unit.create"
        msgDic['type'] = match[1]
        msgDic['lat'] = match[2]
        msgDic['lon'] = match[3]
    elif match[0] == 'move':
        msgDic['action'] = "unit.move"
        msgDic['id'] = match[1]
        msgDic['lat'] = match[2]
        msgDic['lon'] = match[3]
    else:
        continue

    if sess:
        msgDic['sess'] = sess
    if userID:
        msgDic['userID'] = userID

    msg = json.dumps(msgDic)
    print '\x1b[38;5;15m' + "S " + msg + '\033[0m'
    sock.send(msg)

else:
    continue

rec = sock.recv(2048)
try:
    data = json.loads(rec)

    #check for session data
    if data['action'] == 'user.login' and data['status'] == 1:
        sess = data['sess']
        #sess = 'cat'
        userID = data['userID']

    if data['status'] == 1:
        print '\x1b[38;5;46m' + "R " + rec + '\033[0m'
    else:
        print '\x1b[38;5;160m' + "R " + rec + '\033[0m'

```

```
except ValueError:
    print rec

sock.close()

sys.exit(0)
```

Annotated Bibliography

- [1] “Google Cloud Messaging for Android,” <http://developer.android.com/google/gcm/index.html>.

Google Cloud Messaging provides the solution to one of the unimplemented secondary objectives. This guide was useful to determine how simple a solution would be and ultimately influenced the final decision not to implement.

- [2] “Location Strategies,” <http://developer.android.com/guide/topics/location/strategies.html>.

While trying to understand how location providers worked at a low level this guide helped fill in the gaps. It also provided the basis for the final implementation that maintained the best location estimate.

- [3] “Reference: android.location,” <http://developer.android.com/reference/android/location/Location.html>.

API reference pages are invaluable when trying to get an understanding of how best to solve a problem. This reference was particularly useful as location exposes a number of functions, most of which are used within the application.

- [4] “Supporting Different Screen Sizes,” <http://developer.android.com/training/multiscreen/screensizes.html>.

Android provides a wide range of options when customising layouts for different device, this guide neatly explains all possibilities.

- [5] “Android - detect small tablet vs big phone?” <http://stackoverflow.com/a/10080537/794119>, 2012.

A simple solution for a problem that had caused a number of problems while trying to solve. This solution was used directly in the final code base.

- [6] B. Boehm, “A spiral model of software development and enhancement,” *Computer*, vol. 21, no. 5, pp. 61–72, 1988.

Giving an outline description of the spiral model as well different advantages and disadvantages associated with such a model. This helped both understand the model in further detail and also influenced the final decision to opt this style of development.

- [7] comScore, “comScore Reports February 2013 U.S. Smartphone Subscriber Market Share,” http://www.comscore.com/Insights/Press_Releases/2013/4/comScore_Reports_February_2013_U.S._Smartphone_Subscriber_Market_Share, 2013.

This was the most recent source of mobile device statistics. Although it was fairly certain that Android would be the platform of choice it was useful to get a feeling of what market share Android currently has.

- [8] Developer Economics, “Developer tools: The foundations of the app economy,” <http://www.visionmobile.com/product/developer-economics-2013-the-tools-report/>, 2013.

A incredibly detailed insight into mobile applications and the developers that create them. Was important to get an insight into both the market and the environment, both of which were clear from this report.

- [9] Handset Detection, “Where in the World are Android Devices Showing Up?” <http://www.handsetdetection.com/blog/where-in-the-world-are-android-devices-showing-up-infographic/>, 2013.

A well made info graphic giving detailed country based insights into Android device usage.

- [10] Jan Philip Matuschek, “v,” <http://janmatuschek.de/LatitudeLongitudeBoundingCoordinates>.

While trying to calculate geospacial coordinates it was clear that the mathematics were outside of my domain knowledge. This article helped understand how such calculations are devised and how they work. Portions of the example code were adapted and used in the final code base.

- [11] C. Lopes, T. Debeauvais, and A. Valadares, “Restful massively multi-user virtual environments: A feasibility study,” in *Games Innovation Conference (IGIC), 2012 IEEE International*, 2012, pp. 1–4.

Concluding that REST could be used as a architecture for desktop multi-player games motivated me to want to investigate if the same is true for mobile devices. Even though the PULL style technology was not adopted for the final version this paper was used earlier in development.

- [12] MapQuest, “Android Maps API: Developer’s Guide,” <http://developer.mapquest.com/web/products/featured/android-maps-api/documentation>.

These developer guides were invaluable when trying to first integrate MapQuest’s own API.

- [13] —, “Open Directions Service Developer’s Guide,” <http://open.mapquestapi.com/directions/>.

Open direction provides the solution to one of the unimplemented secondary objectives. This guide was useful to determine how simple a solution would be and ultimately influenced the final decision not to implement.

- [14] E. Trevisani and A. Vitaletti, “Cell-id location technique, limits and benefits: an experimental study,” in *Mobile Computing Systems and Applications, 2004. WMCSA 2004. Sixth IEEE Workshop on*, 2004, pp. 51–60.

A great introduction into the topic of cell-ID based location, one of the less well known location providers. It was also interesting to read about further techniques that can be utilized to improve the accuracy of cell-ID based location.
